

In general, Vulgarlang exports three distinct layers:

1. Internal phonological representation
2. Surface spelling / orthography
3. Generated lexicon + grammar metadata

Those are stored in JSON fields like the ones in your file.

For your export in particular:

The phonology layer

Fields like:

- customConsonants
- customVowels
- wordInitialConsonants
- midWordConsonants
- wordFinalConsonants
- illegalCombinations

define the phoneme inventory and phonotactics.

Vulgarlang typically stores phonemes as literal Unicode IPA characters, not escape codes or numbered references. So normally you'd see:

ʒ ɹ ŋ ø '

not:

Ê É¹ Å Ã, Ë

Your file is just misdecoded.

It also allows multigraph phonemes:

- tt
- kk
- ŋd
- etc.

These are treated as single phonological units for generation even if they contain multiple symbols.

The broad word structure layer

Fields like:

C = ...

L = ...

V = ...

S = CV CVL VC

and:

~

are template macros:

- C = consonant class
- V = vowel class
- L = liquid/nasal class
- S = syllable macro

Then words are generated from sequences of S.

Example:

If:

S = CVL

and:

word = SS

you get:

(CVL)(CVL)

Example output:

kra.mon

fel.tun

depending on inventory.

Affix logic

Your export has:

-VC

CV-

IF V# THEN -C ELSE -V

meaning:

suffix:

- vowel + consonant

prefix:

- consonant + vowel

conditional suffix:

if word ends in vowel, append consonant;

otherwise append vowel.

That's morphology logic, not phonetics.

Your:

a > ã
ø > ua
ʒ > j
ɹ > d
...

means:

internal phoneme → written form

Example:

internal:

/ʒøɹ/

written:

juad

This layer can be wildly nonphonetic.

Lexicon entries

Format:

gloss : POS = phonological_form

Example:

apple : nf = 'ɹoton

where:

- gloss = English semantic anchor
- nf = noun feminine
- nm = noun masculine
- adj = adjective
- v = verb
- prep = preposition
- adv = adverb
- conj = conjunction
- det = determiner
- pron = pronoun
- num = numeral

The right side is usually underlying phonological form, not orthographic spelling, unless configured otherwise.

Stress / tone

"stressDropdown":"penultimate"

"mainStress":"leftMost"

"representToneAs":"letter"

This means Vulgarlang is tracking prosody structurally.

Primary stress is encoded directly in entries with:

'

(appearing corrupted as Ë)

For your file specifically

Your language appears to have:

Consonants:

retroflex / rhotic / lateral heavy inventory

Front rounded vowels:

ø

nasalized vowels:

ĩ

complex clusters:

ŋɖ, possibly ɣŋ-like clusters

fairly simple syllable templates:

mostly CV / CVL / VC

strong orthographic transformation layer

One caveat:

that mysterious symbol:

ð☐

(or corrupted ð¼)

is not standard IPA. It may be:

- extIPA,
- Unicode phonetic extension,
- or a private / obscure symbol Vulgarlang accepted literally.

That one needs proper byte reconstruction.

Short version:

Vulgarlang stores literal Unicode phonology, applies class/template generation, then optional

orthographic transformation. Your concept is structurally intact but text encoding corrupted
